Rules of thumb for oil field development

Contributors: Edmund Stephens

The Rules of Thumb for oil field development are intended as order of magnitude evaluation of reservoir volumes, productivity and reservoir performance. They are based on a typical undersaturated light oil in moderate to good quality reservoir, but may be scaled to suit the fluid and reservoir properties required. While not replacing more precise evaluation, these allow for rapid estimation as QC on results and/or as a reasonable starting point for further analysis.

**STOIIP rule of thumb**

The classic STOIIP equation gives the stock tank volume of oil in terms of the net rock volumes and reservoir parameters. Substituting for typical values \( \phi_{avg} 25\%, S_o 0.8 \) and \( B_{oi} \) 1.3 gives the simple rule of thumb:

\[
STOIIP: 1km^2 \times 1m \rightarrow 1MMstb
\]

The rule of thumb is modified to give the ‘rule’ for your field by entering the typical porosity, saturation and shrinkage, usually in the range 0.3 – 1.5:

\[
\text{stb/m}^3 \leftarrow \text{STOIIP}/A.H_{net} = \phi_{avg} \cdot S_o/B_{oi} \times 6.29
\]

**Pl rule of thumb**

The classic well inflow equation gives the productivity index for oil in terms of the reservoir permeability, thickness, viscosity, shrinkage and geometric flow factor. Substituting for typical values \( B_{oi} 1.3, \frac{r_p}{r_w} - 10 \) and no skin gives the simple rule of thumb:

\[
PI: 1D. m/cp \rightarrow 2stb/d/psi
\]

Completion / damage skin modifies the PI as follows

\[
PI \times 1/(1 + 5/10)
\]

**Well count / spacing**

In a water injection development the number of wells required can be estimated from basic data. The premise of the ‘wash cycle equation’ is that a hydrocarbon pore volume should be injected i) at the economically optimal rate, for oil fields typically injecting at ca. 15% pore volume per year; and ii) assuming voidage replacement making a link to oil well performance:

\[
N_{prod \text{ wells}} = \frac{15\% \cdot HCPV}{365 \cdot B_{oi} \cdot Q_{oi}}
\]

Notes
i. Productivity depends on completion type, e.g. sand control, fracring.

ii. The rule does not specify injector numbers, only number of producers, but e.g. in a 5-spot pattern the well spacing \( L \) depends is given by

\[
L_{inj-prod} = 1/2 \sqrt{N_{prod \text{ wells}}/\text{Area}}
\]

**Flooding rule of thumb**

The flood front velocity for a stable displacement is proportional to the applied pressure gradient between producers and injectors or aquifer. Typical values \( \mu_w 0.4 \) cp, \( k_{rw} 0.3, B_{oi} 1.3, S_{om} 0.6 \), gives the simple rule of thumb:

\[
FV: 1D \times 1 \text{ psi/km} \rightarrow 1 \text{ m/yr}
\]

where the flooding velocity

\[
FV = k_{rw} \frac{k_{avg} \Delta P}{\phi \cdot \mu_w \cdot S_{om} \cdot L}
\]

Also of note is how the fluid static gradient \( \Delta \rho.g \) ~ 0.15 psi/ft compares to reservoir gradients:

\[
0.15 \text{ psi/ft} \sim 30 \text{ bar/km}
\]
